A MIXED-INTEGER PDE-CONSTRAINED OPTIMIZATION FORMULATION FOR ELECTROMAGNETIC CLOAKING *

RYAN H. VOGT†, SVEN LEYFFER‡, AND TODD MUNSON§

Abstract. We formulate a mixed-integer partial-differential equation constrained optimization problem for designing an electromagnetic cloak governed by the 2D Helmholtz equation with absorbing boundary conditions. Our formulation is an alternative to the topology optimization formulation of electromagnetic cloak design. We extend the formulation to include uncertainty with respect to the angle of the incidence wave, and we develop a mixed-integer trust-region approach for solving both the deterministic and the uncertain formulation. We present detailed numerical results that show that our trust-region approach obtains effective cloaks.

Key words. PDE-constrained optimization, mixed-integer nonlinear optimization, Helmholtz equation, electromagnetic cloaking.

1 Introduction

Since the study of optics began, the ability to control the properties of light with materials found in nature has been limited. The introduction of metamaterials, which cannot be found in nature, made the creation of electromagnetic cloaks feasible and brought a strong interest to this field of study [17]. The goal of an electromagnetic cloak on an object is for the light to flow around the object, rather than being scattered by the object, causing the object to optically disappear. Numerical simulations and experiments reported in 2006 and 2007 highlighted advancements in the construction of electromagnetic cloaks [5, 7]; and experiments reported in [17] have established the first practical implementation of an electromagnetic cloak over a small-frequency band. While this cloak was unsuccessful in obtaining perfect cloaking of a copper cylinder, the experiments showed the ability to decrease the shadow of an object, getting closer to resembling empty space, thus reinforcing the theory of electromagnetic cloaking and the practicality of an implementation. In [6] the authors presented an in-depth summary of electromagnetic cloaking by means of metamaterials. Highlights include several key experiments, and also a discussion of future directions for electromagnetic cloaking, especially in the area of cloaking for a large frequency band, which has not yet been observed. Recently, experimental observations established the construction of electromagnetic cloaks which are not dependent on prior knowledge of the incidence wave [18].

In this paper, we study the design of electromagnetic cloaks by formulating and solving a mixed-integer partial-differential equation constrained optimization (MIPDECO) problem. The objective is to minimize the integral of the response in the region we wish to cloak. The constraints include a 2D Helmholtz equation with absorbing boundary conditions for each component of the complex-valued scattering

wave that are parameterized by the design of the electromagnetic cloak. The design is obtained by using binary variables that determine whether a cell in the system is filled with material or not. The cloak design depends on the region to cloak, the angle of the incidence wave, the cloaking material, and the wavenumber.

We extend the cloak design by including uncertainty with respect to the angle of attack, leading to a stochastic programming formulation where we minimize the expected value of the objective function with respect to a discrete set of angles.

We solve the resulting combinatorial optimization problem in two steps. The first step relaxes the binary variables, solves the relaxation, and applies a rounding heuristic to obtain an initial design. The second step consists of a set of trust-region iterations to improve upon the initial design. Our approach replaces the large-scale mixed-integer nonlinear program (MINLP) by a sequence of easier linear knapsack problems that can be solved in polynomial time.

Paper Outline. In Section 2 we define the infinite-dimensional electromagnetic cloaking problem for a nominal wave angle. We then extend this formulation to an optimization problem under uncertainty that can account for uncertainty in the angle of the incidence wave, and we compute sensitivities with respect to the design variables that are needed in our optimization approach. In Section 3 we derive a finite-dimensional optimal design problem by discretizing the PDE using a finite-element approach, resulting in a large-scale MINLP. Next, we present an approach to solve the relaxed MINLP. In Section 4 we motivate a simple rounding heuristic and describe our trust-region steepest-descent algorithm. We provide numerical experiments in Section 5 to demonstrate the success of our trust-region method, and we comment on the computational effort to solve our problems. We conclude with a brief summary in Section 6. Detailed numerical results are presented in the electronic supplement SM1.

2 Electromagnetic Cloaking Design

In this section we review the infinite-dimensional cloaking design problem. We extend the nominal design and propose a stochastic optimization formulation for the design under uncertainty. We also show how adjoints of the problems are derived. These adjoints are needed for the solution of the continuous relaxation and for our proposed trust-region method.

2.1 Formulation of the Nominal Electromagnetic Cloaking Problem

We consider the design of an electromagnetic cloak from [11], where we aim to determine the optimal topology. We let $D \subset \mathbb{R}^2$ be the computational domain and $D_0 \subset D$ be the part of the domain that we wish to cloak. We let $\hat{D} \subset D - D_0$ be the subregion in which we can design the cloak and $\Omega \subset \hat{D}$ be the topology of the cloak. The optimal topology is determined by solving the following topology optimization problem that aims to minimize the response due to the incidence wave in $D_0$ subject to the Helmholtz equation in $D$:

$$\begin{align*}
\text{minimize} & \quad 1/2 \| u + \bar{u}_\theta \|^2_{2,D_0} \\
\text{subject to} & \quad -\Delta u - k_0^2 (1 + q_{\Omega}) u = k_0^2 1_{\Omega} \bar{u}_\theta \quad \text{in } D \\
& \quad \frac{\partial u}{\partial n} - ik_0 u = 0 \quad \text{on } \partial D,
\end{align*}$$

(2.1)

where $i = \sqrt{-1}$, $\partial D$ is the boundary of the computational domain and

$$\bar{u}_\theta(x, y) = \exp(ik_0(x \cos(\theta) + y \sin(\theta)))$$

(2.2)
is the incidence wave in direction \( d = (\cos(\theta), \sin(\theta)) \), with wave number \( k_0 \). The angle \( \theta \) at which the incidence wave approaches the cloak is measured from the x-axis, and we refer to \( \theta \) as the nominal angle of attack. The state variable \( u \) represents the electromagnetic field intensity, and the parameter \( q \) is the electromagnetic permittivity difference between \( \Omega \), the part of the cloak filled with material, and \( D - \Omega \) the part of the cloak without material.

When manufacturing cloaks, there is typically a lower bound on the size of the features in the cloak, \( \Omega \). We partition the cloak \( \Omega \) into a finite number of uniform squares, \( \Omega_n \), for \( n = 1, \ldots, N \). We refer to this partition as the control mesh and assume that

\[
\Omega = \bigcup_{n=1}^{N} \Omega_n \quad \text{and} \quad (\Omega_n \setminus \partial \Omega_n) \cap (\Omega_p \setminus \partial \Omega_p) = \emptyset \text{ for } n \neq p;
\]

see Figure 1a for an illustration.

We represent the decision of whether or not to fill a square \( \Omega_n \subset \Omega \) by a binary (control) variable \( v_n \in \{0, 1\} \) for \( n = 1, \ldots, N \), and we define the indicator function \( 1_{\Omega_n} \) for \( \Omega_n \) as

\[
1_{\Omega_n}(x, y) = \begin{cases} 
1 & \text{if } (x, y) \in \Omega_n \\
0 & \text{otherwise},
\end{cases}
\]

for \( n = 1 \ldots N \). The resulting reformulation of (2.1) can be rewritten as the MIPDECO

\[
\min_{u, v, w} \frac{1}{2} \| u + \bar{u}_\theta \|^2_{L^2(D)}
\]

subject to

\[
- \Delta u - k_0^2 (1 + qw)u = k_0^2 qwu_\theta \quad \text{in } D
\]

\[
\frac{\partial u}{\partial n} - ik_0 u = 0 \quad \text{on } \partial D
\]

\[
w = \sum_{n=1}^{N} v_n 1_{\Omega_n \setminus \partial \Omega_n}
\]

\[
v_n \in \{0, 1\} \quad \forall n = 1, \ldots, N,
\]

where the defined control, \( w \), now takes the place of the topological variable, \( \Omega \). In this formulation, we have a fixed finite number of binary variables \( v_n \) that represent the design. Because \( u, \bar{u}_\theta : \mathbb{R}^2 \rightarrow \mathbb{C} \) is complex valued, we split \( u \) and \( \bar{u}_\theta \) into its real and imaginary parts, \( u = u_{Re} + i u_{Im} \), resulting in two separate PDEs for the real and the imaginary part, respectively.

In general, we have an \( m \times m \) control mesh made up of \( N = m^2 \) binary variables.

We illustrate a sample design in Figure 1a, where red indicates material and blue indicates no material.

### 2.2 Optimal Design for Electromagnetic Cloaking under Uncertainty

Here, we extend the optimal design problem to account for uncertainty in the incidence angle or angle of attack, \( \theta \). We formulate an optimization problem to create a design that can effectively cloak a given region even if the incidence angle of the wave changes.

To account for uncertainty in the design, we generalize problem (2.4) to allow a range of incidence angles \( \theta \) and we regard the incidence angle as a random variable. We can then formulate an optimization problem that minimizes, for example, the expected value of the effectiveness of the cloak. We let \((\Theta, \mathcal{F}, P)\) be a triple of sample
space, $\sigma$-algebra, and probability measure, and we formulate the following stochastic optimization problem:

$$\begin{align*}
\text{minimize} & \quad J(u, v, w) = \mathbb{E}_\theta \left[ \frac{1}{2} \| u_\theta + \bar{u}_\theta \|^2_{L^2(D_0)} \right] \\
\text{subject to} & \quad -\Delta u_\theta - k_0^2 (1 + qw) u_\theta = k_0^2 qw \bar{u}_\theta \quad \text{in } D, \ \forall \theta \in \Theta \\
& \quad \frac{\partial u_\theta}{\partial n} - ik_0 u_\theta = 0 \quad \text{on } \partial D, \ \forall \theta \in \Theta \\
& \quad w = \sum_{n=1}^N v_n 1_{\Omega_n \setminus \partial \Omega_n} \\
& \quad v_n = \{0, 1\} \quad \forall n = 1, \ldots, N,
\end{align*}$$

(2.5)

where $\mathbb{E}_\theta[\cdot]$ is the expectation with respect to the random variable $\theta$ and $u_\theta = u_\theta(v)$ is the solution of the PDE for a given control $v$, and incidence angle, $\theta$. Problem (2.5) has a structure similar to that of a two-stage stochastic program if we interpret the controls $w$ and $v$ as the first-stage decision variables, and the states $u_\theta$ as the second-stage variables. However, there is no optimization in the second stage because $w$, $v$, and $\theta$ uniquely determine $u_\theta$. To approximate the expectation in (2.5), we select a finite set of $s$ angles denoted by the set $\Theta(s) \subset \Theta$, for example,

$$\Theta(s) = \left\{ \theta_j \mid \theta_j = \frac{\pi j}{2s}, \ j = 0, \ldots, s \right\},$$

and we replace the expectation by the sample average mean. We assume that each $\theta_j$
has a probability $P_j$ of occurring, and we assume that all angles of attack are equally likely, $P_j = \frac{1}{|\Theta(s)|}$ (though this assumption is readily relaxed). We can interpret $\Theta(s)$ as a discretization of a uniform distribution over the interval of interest. We now rewrite our cloaking optimization problem for the finite set $\Theta(s)$ as

$$
\text{minimize}_{u^{(j)}, v, w} \quad J(u^{(j)}, v, w) = \frac{1}{2|\Theta(s)|} \sum_{j=0}^{s} \|u^{(j)} + \bar{u}^{(j)}\|_{2D_0}^2
$$

subject to

$$
-\Delta u^{(j)} - k_0^2 (1 + qw) u^{(j)} = k_0^2 qw\bar{u}^{(j)} \quad \text{in } D, \quad \forall j = 0, \ldots, s
$$

$$
\frac{\partial u^{(j)}}{\partial n} - ik_0 u^{(j)} = 0 \quad \text{on } \partial D, \quad \forall j = 0, \ldots, s
$$

$$
w = \sum_{n=1}^{N} v_n \mathbb{I}_{\Omega_n \setminus \partial \Omega_n}
$$

$$
v_n = \{0, 1\} \quad \forall n = 1, \ldots, N.
$$

where $u^{(j)}$ is the state corresponding to the $j$th scenario, $\theta_j$, and the incidence wave associated with $\theta_j$ is defined as

$$
\bar{u}^{(j)}(x, y) = \exp(ik_0(x \cos(\theta_j) + y \sin(\theta_j))), \quad \forall j = 0, \ldots, s.
$$

This stochastic program has $2|\Theta(s)|$ state variables and $2|\Theta(s)|$ adjoint variables. The evaluation of the objective function and gradient of (2.5) requires the solution of $4|\Theta(s)|$ PDEs for each fixed $v$.

### 2.3 Weak Adjoint and Gradient Equations

Our method for solving (2.6) is based on solving the continuous relaxation followed by a rounding step and an incremental trust-region improvement algorithm. Both steps require computing gradients with respect to the control variables $v$. Here, we present the derivation of the weak state and weak adjoint equation for the uncertain problem (the derivation for the easier nominal problem follows in a similar way). In addition we provide the strong gradient derivation for (2.5) using the adjoint approach for calculating the gradient for the continuous relaxation ($0 \leq v \leq 1$). We begin by formally defining the strong Lagrangian $\mathcal{L}$ of (2.6) as

$$
\mathcal{L}(u^{(j)}_{\text{Re}}, u^{(j)}_{\text{Im}}, v; \lambda^{(j)}_{\text{Re}}, \lambda^{(j)}_{\text{Im}}, \theta) = \frac{1}{2|\Theta(s)|} \left( \sum_{j=0}^{s} \left( \int_{D_0} \left( (u^{(j)}_{\text{Re}} + \bar{u}^{(j)}_{\text{Re}})^2 + (u^{(j)}_{\text{Im}} + \bar{u}^{(j)}_{\text{Im}})^2 \right) dD_0 \right) - \sum_{j=0}^{s} \left\langle \lambda^{(j)}_{\text{Re}}, \left( -\Delta u^{(j)}_{\text{Re}} - k_0^2 (1 + qw) u^{(j)}_{\text{Re}} - k_0^2 qw\bar{u}^{(j)}_{\text{Re}} \right) \right\rangle_{L^2(D)} - \sum_{j=0}^{s} \left\langle \lambda^{(j)}_{\text{Im}}, \left( -\Delta u^{(j)}_{\text{Im}} - k_0^2 (1 + qw) u^{(j)}_{\text{Im}} - k_0^2 qw\bar{u}^{(j)}_{\text{Im}} \right) \right\rangle_{L^2(D)} \right)
$$

where $\langle \cdot, \cdot \rangle_{L^2(D)}$ is the $L^2$ inner product over $D$ and $\lambda^{(j)}_{\text{Re}}, \lambda^{(j)}_{\text{Im}}$ are the adjoint variables for the $j$th real and imaginary state equation respectively. In (2.8) the strong Lagrangian is defined: we assume that the pairs $u^{(j)}_{\text{Re}}, u^{(j)}_{\text{Im}} \in C^2(D)$ are twice continuously differentiable. We weaken this regularity assumption because we intend to search for weak solutions with the finite-element method. Next, we derive the weak
form of the Lagrangian by applying Green’s theorem to the two constraint terms:

\[ \sum_{j=0}^{s} \left( \lambda_{\text{Re}}^{(j)} \left( -\Delta u_{\text{Re}}^{(j)} - k_0^2 (1 + qw) u_{\text{Re}}^{(j)} - k_0^2 q w \bar{u}_{\text{Re}}^{(j)} \right) \right)_{L^2(D)} \]

\[ = \sum_{j=0}^{s} \left[ \int_D \lambda_{\text{Re}}^{(j)} \left( -\Delta u_{\text{Re}}^{(j)} - k_0^2 (1 + qw) u_{\text{Re}}^{(j)} - k_0^2 q w \bar{u}_{\text{Re}}^{(j)} \right) dD \right] \]

\[ = \sum_{j=0}^{s} \left[ \int_D \nabla u_{\text{Re}}^{(j)} \cdot \nabla \lambda_{\text{Re}}^{(j)} dD + \int_{\partial D} k_0 u_{\text{im}}^{(j)} \lambda_{\text{Re}}^{(j)} d\partial D \right. \]

\[ - \int_D \lambda_{\text{Re}}^{(j)} \left( k_0^2 (1 + qw) u_{\text{im}}^{(j)} + k_0^2 q w \bar{u}_{\text{im}}^{(j)} \right) dD \right] \]

and

\[ \sum_{j=0}^{s} \left( \lambda_{\text{Im}}^{(j)} \left( -\Delta u_{\text{Im}}^{(j)} - k_0^2 (1 + qw) u_{\text{Im}}^{(j)} - k_0^2 q w \bar{u}_{\text{Im}}^{(j)} \right) \right)_{L^2(D)} \]

\[ = \sum_{j=0}^{s} \left[ \int_D \lambda_{\text{Im}}^{(j)} \left( -\Delta u_{\text{Im}}^{(j)} - k_0^2 (1 + qw) u_{\text{Im}}^{(j)} - k_0^2 q w \bar{u}_{\text{Im}}^{(j)} \right) dD \right] \]

\[ = \sum_{j=0}^{s} \left[ \int_D \nabla u_{\text{Im}}^{(j)} \cdot \nabla \lambda_{\text{Im}}^{(j)} dD - \int_{\partial D} k_0 u_{\text{im}}^{(j)} \lambda_{\text{Im}}^{(j)} d\partial D \right. \]

\[ - \int_D \lambda_{\text{Im}}^{(j)} \left( k_0^2 (1 + qw) u_{\text{im}}^{(j)} + k_0^2 q w \bar{u}_{\text{im}}^{(j)} \right) dD \right] \]

We substitute (2.9) and (2.10) into (2.8) and obtain the weak Lagrangian:

\[ \mathcal{L}(u_{\text{Re}}^{(j)}, u_{\text{Im}}^{(j)}, v, \lambda_{\text{Re}}^{(j)}, \lambda_{\text{Im}}^{(j)}, \theta) \]

\[ = \frac{1}{2 |\Theta(s)|} \left( \sum_{j=0}^{s} \left( \int_{D_0} \left( u_{\text{Re}}^{(j)} + \bar{u}_{\text{Re}}^{(j)} \right)^2 + \left( u_{\text{Im}}^{(j)} + \bar{u}_{\text{Im}}^{(j)} \right)^2 dD_0 \right) \right) \]

\[ + \sum_{j=0}^{s} \left[ \int_D \nabla u_{\text{Re}}^{(j)} \cdot \nabla \lambda_{\text{Re}}^{(j)} dD + \int_{\partial D} k_0 u_{\text{im}}^{(j)} \lambda_{\text{Re}}^{(j)} d\partial D \right. \]

\[ - \int_D \lambda_{\text{Re}}^{(j)} \left( k_0^2 (1 + qw) u_{\text{Re}}^{(j)} + k_0^2 q w \bar{u}_{\text{Re}}^{(j)} \right) dD \right] \]

\[ + \sum_{j=0}^{s} \left[ \int_D \nabla u_{\text{Im}}^{(j)} \cdot \nabla \lambda_{\text{Im}}^{(j)} dD - \int_{\partial D} k_0 u_{\text{im}}^{(j)} \lambda_{\text{Im}}^{(j)} d\partial D \right. \]

\[ - \int_D \lambda_{\text{Im}}^{(j)} \left( k_0^2 (1 + qw) u_{\text{im}}^{(j)} + k_0^2 q w \bar{u}_{\text{Im}}^{(j)} \right) dD \right] \].

In the final form (2.11), we assume that \( u_{\text{Re}}^{(j)}, u_{\text{Im}}^{(j)} \in H^1(D) \), where \( H^1(D) := W^{1,2} \) is the Sobolev space of all functions that are \( L^2(D) \) (square integrable) and whose weak derivative in the sense of distributions is also in \( L^2(D) \). To find the sensitivities of the objective function, \( \mathcal{J} \), with respect to \( v \), we exploit the fact that there exists a unique \( w \) for any choice of \( v \) and that (under suitable conditions on \( k_0 \)) there exists a unique \( u \) for any \( v \). We start by deriving the weak state equations, which are obtained by taking variations with respect to \( \lambda_{\text{Re}}^{(j)}, \lambda_{\text{Im}}^{(j)} \) for all \( j = 0, \ldots, s \):

\[ 0 = \frac{\partial \mathcal{J}}{\partial \lambda_{\text{Re}}^{(j)}} = \int_D \nabla u_{\text{Re}}^{(j)} \cdot \nabla \lambda_{\text{Re}}^{(j)} dD + \int_{\partial D} k_0 u_{\text{im}}^{(j)} \lambda_{\text{Re}}^{(j)} d\partial D \]
differentiating (2.11) with respect to process, we can produce the strong gradient (which is also the weak gradient) by

\[
\begin{align*}
-\int_D \tilde{\lambda}_{\text{Re}}^{(j)}(1 + qw)u_{\text{Re}}^{(j)} dD, \\
0 = \mathcal{L}_{\text{Im}}^{(j)}[\tilde{\lambda}_{\text{Im}}^{(j)}] = \int_D \nabla u_{\text{Im}}^{(j)} \cdot \nabla \tilde{\lambda}_{\text{Im}}^{(j)} dD - \int_{\partial D} k_0 u_{\text{Re}}^{(j)} \tilde{\lambda}_{\text{Im}}^{(j)} d\partial D
\end{align*}
\]

(2.13) \( \forall \tilde{\lambda}_{\text{Re}}^{(j)} \in H^1(D) \)

We note that the weak state equation pair has a unique solution in \( H^1(D) \) [11]. Once we have solved this state equation pair, we can calculate the adjoint pairs, \( (\lambda_{\text{Re}}^{(j)}, \lambda_{\text{Im}}^{(j)}) \), by solving the weak adjoint equations obtained by taking variations with respect to \( \tilde{u}_{\text{Re}}^{(j)}, \tilde{u}_{\text{Im}}^{(j)} \) for all \( j = 0, \ldots, s \):

\[
\begin{align*}
0 = \mathcal{L}_{\text{Re}}^{(j)}[\tilde{u}_{\text{Re}}^{(j)}] &= \frac{1}{|\Theta(s)|} \int_{D_0} (u_{\text{Re}}^{(j)} + \tilde{u}_{\text{Re}}^{(j)}) \tilde{u}_{\text{Re}}^{(j)} dD_0 \\
+ \int_D \nabla \tilde{u}_{\text{Re}}^{(j)} \cdot \nabla \lambda_{\text{Re}}^{(j)} dD - \int_D \lambda_{\text{Re}}^{(j)} k_0^2(1 + qw)\tilde{u}_{\text{Re}}^{(j)} dD \\
- \int_{\partial D} k_0 \tilde{u}_{\text{Re}}^{(j)} \lambda_{\text{Im}}^{(j)} d\partial D, \\
0 = \mathcal{L}_{\text{Im}}^{(j)}[\tilde{u}_{\text{Im}}^{(j)}] &= \frac{1}{|\Theta(s)|} \int_{D_0} (u_{\text{Im}}^{(j)} + \tilde{u}_{\text{Im}}^{(j)}) \tilde{u}_{\text{Im}}^{(j)} dD_0 \\
+ \int_D \nabla \tilde{u}_{\text{Im}}^{(j)} \cdot \nabla \lambda_{\text{Im}}^{(j)} dD - \int_D \lambda_{\text{Im}}^{(j)} k_0^2(1 + qw)\tilde{u}_{\text{Im}}^{(j)} dD \\
+ \int_{\partial D} k_0 \tilde{u}_{\text{Im}}^{(j)} \lambda_{\text{Re}}^{(j)} d\partial D, \\
\forall \tilde{u}_{\text{Re}}^{(j)} \in H^1(D), \
\forall \tilde{u}_{\text{Im}}^{(j)} \in H^1(D).
\end{align*}
\]

(2.14) (2.15)

The proof for the existence and uniqueness of the solution to general elliptic equations with Robin boundary conditions in \( H^1(D) \) can be found in [16] and extends to the adjoint equation pair, which differs from the state equation pair only in its source term. An argument similar to [11] can then be applied to show the existence and uniqueness of the solutions.

After we have calculated the state and adjoint variables for all scenarios, we can assemble the \( n \)th component of the gradient of the Lagrangian with respect to \( v_n \):

\[
(\nabla_v \mathcal{L})_n = -\sum_{j=0}^s \int_{\Omega_n} \left( k_0^2(1 + qw)u_{\text{Re}}^{(j)} + k_0^2(1 + qw)u_{\text{Im}}^{(j)} \right) d\Omega_n.
\]

(2.16)

One can show, as illustrated in [19, Lemma 2.30], that the weak gradient equation \( \mathcal{L}_v[\tilde{v}] \) satisfies

\[
\mathcal{L}_v[\tilde{v}] = \langle \nabla_v \mathcal{L}, \tilde{v} \rangle_{\mathbb{R}^N} = \langle \tilde{J}'(v), \tilde{v} \rangle_{\mathbb{R}^N} \forall \tilde{v} \in \mathbb{R}^N.
\]

(2.17)

Because \( v \) is a continuous finite-dimensional decision variable during the relaxation process, we can produce the strong gradient (which is also the weak gradient) by differentiating (2.11) with respect to \( v \). Following [19, Lemma 2.21],

\[
(\tilde{J}'(v)^*)^T (v - v^*) \geq 0 \forall v \in V = \{ v : 0 \leq v \leq 1, v \in \mathbb{R}^N \}
\]

(2.18)

are the necessary optimality conditions of the reduced space formulation,

\[
\begin{align*}
\text{minimize}_{0 \leq v \leq 1} \tilde{J}(v) &= \frac{1}{2|\Theta(s)|} \sum_{j=0}^s \| S\eta_j(v) + \tilde{u}^{(j)} \|_{L^2(D_0)}^2, \\
\end{align*}
\]

(2.19)
with $S_{\theta_j}$ being the solution operator $S_j : v \rightarrow u_j$ for incidence angle $\theta_j$.

3 Solving the Continuous Optimal Design Problem

In this section we describe our discretization and then show how we solve the continuous design problem using a reduced-space method.

3.1 Discretization of State and Adjoint Equations

Here we show how to solve discretizations of the state and adjoint PDEs and compute (discretized) gradients that can be used in a reduced-space approach. To solve the state and adjoint PDEs we use a Galerkin FEM [12]. We decompose our physical domain $D$ into a computational domain made up of uniform triangle elements, $E_i$, with length and height $h$ as illustrated in Figure 1b, such that

$$D = \bigcup_i E_i \quad \text{and} \quad (E_i \setminus \partial E_i) \cap (E_j \setminus \partial E_j) = \emptyset, \forall i \neq j.$$  

We also assume that each control element $\Omega_n$ covers a fixed number of finite elements $E_i$, as shown in Figure 1b.

We construct an approximate solution to the state and adjoint variables using piecewise linear test functions on our finite elements, giving linear test functions that have compact support on their element. We then approximate the solution by a linear combination of the test functions for the $j$th scenario:

$$u_{\text{Re}}^h = \sum_{i=1}^{R(h)} u_{\text{Re}}^{i,j} \phi_i, \quad u_{\text{Im}}^h = \sum_{i=1}^{R(h)} u_{\text{Im}}^{i,j} \phi_i, \quad \lambda_{\text{Re}}^h = \sum_{i=1}^{R(h)} \lambda_{\text{Re}}^{i,j} \phi_i, \quad \lambda_{\text{Im}}^h = \sum_{i=1}^{R(h)} \lambda_{\text{Im}}^{i,j} \phi_i,$$

where $u_{\text{Re}}^{i,j}, u_{\text{Im}}^{i,j}, \lambda_{\text{Re}}^{i,j}$, and $\lambda_{\text{Im}}^{i,j}$ are the coefficient vectors of our expansion that are determined by the FEM (we use boldface to indicate finite-dimensional vectors in the remainder). Here, $R(h)$ is the number of elements in the discretization for a fixed step size $h$, and we choose piecewise linear test functions.

Given a $v$ (and hence, $w$), we substitute (3.2) into (2.12), (2.13), (2.14), and (2.15). This approach allows us to find the coefficients by solving a linear system of equations that defines our approximate solution to the state and adjoint equations over the domain $D$. The resulting linear systems of equations (for fixed $v$) is obtained by substituting our trial solution into the real and imaginary state equations

$$A(v) u_{\text{Re}}^j = f_{\text{Re}}^j(v), \quad B(v) u_{\text{Im}}^j = f_{\text{Im}}^j(v)$$

for the $j$th incidence angle, where

$$A(v) = \int_D \nabla \phi_i \cdot \nabla \phi_j dD + \int_{\partial D} k_0 \phi_i \phi_j \partial \tilde{D} - \int_D k_0^2 \left(1 + q \left( \sum_{n=1}^N v_n z_{\Omega_n \setminus \partial \Omega_n} \right) \right) \phi_i \phi_j dD,$$

$$B(v) = \int_{\partial D} k_0 \phi_i \phi_j \partial \tilde{D},$$

and

$$f_{\text{Re}}^j(v) = \int_D k_0^2 q \left( \sum_{n=1}^N v_n z_{\Omega_n \setminus \partial \Omega_n} \right) \tilde{u}_{\text{Re}}^{(j)} \phi_j dD.$$

We note $f_{\text{Im}}^j$ is defined analogously by replacing $\tilde{u}_{\text{Re}}^{(j)}$ by $\tilde{u}_{\text{Im}}^{(j)}$. 

8
Next we write down the systems for the adjoint variables associated with the real and imaginary adjoint equations. We note that the weak adjoint equations depend on the solution to the state equations. In the discretized adjoint equations we use the discretized solution found by solving the state equations as an approximation to the state. The system for the adjoint variables is

\[
\begin{bmatrix}
A(v) & -B(v) \\
B(v) & A(v)
\end{bmatrix}
\begin{bmatrix}
\lambda_{Re}^j \\
\lambda_{Im}^j
\end{bmatrix}
= \begin{bmatrix}
g_{Re}^j(v) \\
g_{Im}^j(v)
\end{bmatrix}
\]

for the \(j\)th incidence angle, where

\[
\begin{align*}
ge_{Re}^j(u) &= -\frac{1}{|\Theta(s)|} \int_{D_0} (u_{h,j}^{Re} + \bar{u}_{Re}^{(j)}) \phi_d dD_0 \\
ge_{Im}^j(u) &= -\frac{1}{|\Theta(s)|} \int_{D_0} (u_{h,j}^{Im} + \bar{u}_{Im}^{(j)}) \phi_d dD_0
\end{align*}
\]

are affine functions of the states, \(u\).

Once we have found the solution to the state and adjoint equations, we construct an approximation of the \(n\)th component of the reduced gradient, \(\hat{J}_{h}^{(v)}\), by using a tensorized two-point Gauss-Legendre quadrature rule to approximate

\[
\nabla_v \hat{J}_{h}^{(v)} = -\frac{1}{\Theta(s)} \sum_{j=0}^{s} \int_{\Omega_n} \left( k_0 q \left( u_{h,j}^{Re} \lambda_{Re}^{h,j} + u_{h,j}^{Im} \lambda_{Im}^{h,j} \right) + k_0 q \left( \bar{u}_{Re}^{h,j} \lambda_{Re}^{h,j} + \bar{u}_{Im}^{h,j} \lambda_{Im}^{h,j} \right) \right) d\Omega_n.
\]

to order \(O(h^2)\), which is consistent with the discretization error of the PDEs.

### 3.2 Reduced-Space Method for Continuous Design

The derivation in the preceding section shows that we can write the finite-dimensional approximation of (2.4) as

\[
\begin{align*}
\min_{v \in [0,1]^N} \hat{J}_{h}^{(v)} &= \frac{1}{2} \sum_{j=0}^{s} \left\| S_{\theta_j}^{h}(v) + \bar{u}_h^{(j)} \right\|_{2, D_0}^2, \\
\end{align*}
\]

where \(S_{\theta_j}^{h}(v)\) is the solution operator for the FEM mesh of size \(h\) given by the system (3.3) with angle \(\theta_j\). The derivation of the reduced gradient, \(\nabla_v \hat{J}_{h}^{(v)}\), is given in (3.1), and we apply a reduced-space optimization approach using a quasi-Newton approximation of the Hessian.

We note that the structure of the discretized state and adjoint equations (3.3) and (3.4), respectively, implies that this optimization problem is nonconvex, because the state equations are bilinear in \(v\) and \(u\). We investigate the effect of this nonconvexity in Section 5.

### 4 Solving the Mixed-Integer Design Problem

The finite-dimensional approximation of the nominal and uncertain MIPDECO (2.4) and (2.5), respectively, become finite-dimensional pure integer nonlinear optimization problems:

\[
\begin{align*}
\min_{v \in \{0,1\}^N} \hat{J}_{h}^{(v)} &= \frac{1}{2} \left\| S_{\theta}^{h}(v) + \bar{u}_h \right\|_{2, D_0}, \\
\end{align*}
\]
and

\[ (4.2) \min_{v \in \{0,1\}^N} J^h(v) = \frac{1}{2\|\Theta(s)\|} \sum_{j=0}^s \|S^h_j(v) + \bar{u}^{(j)}\|_2^2, \]

respectively, where \( S^h_j(v) \) is the solution operator defined in (3.3).

The structure of (4.1) and (4.2) involving the solution operators \( S^h_j(v) \) makes it difficult to apply the standard MINLP solvers (e.g., [1, 4, 13]) that require analytic expressions for all the functions. One approach might be to include the discretized PDEs (3.3) and (3.4) directly as constraints. However, we found on other MIPDECOs that such an approach does not result in an MINLP that can be solved by modern MINLP solvers. Hence we consider a heuristic approach as described next.

Our approach for solving the MIPDECOs, (4.1) and (4.2), is a two-phase method. We first solve a relaxation, (2.19) and round its solution. We then apply a discrete steepest-descent trust-region approach to improve this rounded solution. Our approach builds on the method in [10] and can be interpreted as a rounding heuristic followed by repeated application of local branching [9, 14]. Unlike local branching, however, we use only first-order information to solve a sequence of approximations enforcing descent from one iteration to the next. As a result, each trust-region subproblem requires the solution of the discretized forward and adjoint PDEs, (3.3) and (3.4), respectively, making it computationally efficient for MIPDECOs. Moreover, the trust-region problem itself can be solved efficiently as a knapsack problem.

4.1 Rounding Heuristic After solving the relaxation, we use a rounding heuristic with rounding threshold \( \tau \).

\[ R_{\tau}(v_n) = \begin{cases} 1 & \text{if } v_n \geq \tau \\ 0 & \text{otherwise.} \end{cases} \]

A popular rounding heuristic is \( \tau = 0.5 \). However, we chose \( \tau = 0.8 \). We have observed in our numerical computation that using this value of \( \tau \) yields an objective value that is at least 10 percent lower than using \( \tau = 0.5 \).

4.2 Steepest-Descent Trust-Region for MIPDECO Here we describe our steepest-descent trust-region approach to improve the rounded solution. The trust-region algorithm can use any feasible \( v \in \{0,1\}^N \) as a starting guess. However, we use the rounded solution of the continuous relaxation (2.19). On the \( k \)th iteration, the algorithm tries to produce a better design by changing at most \( \Delta_k \) elements of \( v^{(k)} \) to improve the cloaking capability of our design. The algorithm terminates once \( \Delta_k < 1 \), which means that no local improvement could be found and reducing \( \Delta_k \) further would not yield a better point. The algorithm is shown in Algorithm 4.1.

We interpret Algorithm 4.1 as a trust-region method for solving MIPDECOs. We choose the \( l_1 \)-norm trust region because it is equivalent to the hamming distance between \( v \) and \( v^{(k)} \), and hence floor (\( \Delta_k \)) corresponds to the maximum number of components of \( v \) that can change from their current value \( v^{(k)} \). One can see easily that the trust-region constraint \( \|v - v^{(k)}\|_1 \leq \Delta_k \) is equivalent to the following affine constraint,

\[ \sum_{i=0}^N \sum_{v_i^{(k)} = 0}^N v_i + \sum_{i=1}^N (1 - v_i) \leq \Delta_k, \]
resulting in a knapsack constraint. We note that the binary knapsack problem can be solved in polynomial time. The step acceptance and step rejection criteria are taken directly from the nonlinear trust-region method; see, for example, [15].

5 Numerical Experiments In this section we describe our experience in solving the nominal cloak design (4.1) and the cloak design under uncertainty (4.2). We start by stating the common features of both experiments. We examine the convexity properties of our design problem and then present the results for the nominal and uncertain design in turn.

5.1 Experimental Setup We consider the cloaking of three different domains $D^1_0$, $D^2_0$, and $D^3_0$ given by

\[
D^1_0 = \{x, y \mid -0.6 \leq x \leq 0.6, 0.7 \leq y \leq 1\} \quad \text{(Rectangle)}
\]

\[
D^2_0 = \{x, y \mid 0.7 \leq x \leq 1, 0.7 \leq y \leq 1\} \quad \text{(Square)}
\]

\[
D^3_0 = \{x, y \mid (x - .85)^2 + (y - .85)^2 \leq (.1)^2\} \quad \text{(Circle)}
\]

which are illustrated in Figure 2. We run all our tests using a MacOS desktop with a 4-core Intel processor working at 3.3 GHz. We use the FEniCS package in Python [2] version 2017.2.0 to solve the state and adjoint PDEs using piecewise linear basis functions, which uses PETSc [3] for the linear algebra. In addition we use the FEniCS default two-point Gauss quadrature method to build the components of the gradient. To solve the relaxation, we use the Toolkit for Advanced Optimization...
Fig. 2: Illustration of the three domains to be cloaked. The computational domain, $D$, is given in yellow. The domain $\Omega$ where the cloak is constructed is given in red. The domain that we aim to cloak is given in green for the instances $D_0^1$, $D_0^2$, and $D_0^3$.

(TAO) [8] with the “blmvm” solver, which is a limited-memory backtracking quasi-Newton method for solving bound-constrained problems. We use CPLEX 12.8.0.0 to solve our trust-region knapsack problem. In our trust-region method, we use $\bar{\rho} = .75$, as recommended by [15], and an initial trust-region radius of $\Delta_0 = 256$. All numerical experiments use the following set of common parameters: wave number $k_0 = 6\pi$, material constant $q = 0.75$, and cloak location $p_D \in \hat{\Omega}$, where

$$\Omega = [-1,1] \times [-1,1] \quad \text{and} \quad \hat{\Omega} = \left[-\frac{5}{8}, \frac{5}{8}\right] \times \left[-\frac{5}{8}, \frac{5}{8}\right].$$

Preliminary numerical simulations indicate that a $128 \times 128$ mesh of finite elements is the best balance between an efficient solution of the state and adjoint equations and a reliable gradient evaluation. We create six test problems each for the nominal and uncertain design by taking the three cloaking regions from (5.1) and two incidence angles for each region, namely, $\theta = \pi/4$ and $\theta = \pi/2$ in the nominal design. In the case of the design under uncertainty, we consider the same two nominal angles with an uncertainty set of $\pm \pi/4$, giving $\theta \in [0, \pi/2]$ and $\theta \in [\pi/4, 3\pi/4]$, respectively.

5.2 Effect of the Nonconvexity We investigate the nonconvexity of our optimal design problem by defining a parametric function $w : [0,1] \to L^2(\Omega)$,

$$w(t)(x,y) = tw_1 + (1-t)w_2, \quad \text{where} \quad w_k = \sum_{n=1}^{N} v_n^{k} 1_{\Omega_n \setminus \hat{\Omega}_n}, \quad \text{for} \quad k = 1, 2,$$

for the particular choice

$$v_n^1 = \begin{cases} 1 & n \text{ even} \\ 0 & n \text{ odd} \end{cases} \quad \text{and} \quad v_n^2 = \begin{cases} 1 & n \text{ odd} \\ 0 & n \text{ even}. \end{cases}$$

It follows that $0 \leq w(t) \leq 1$, $\forall t \in [0,1]$, and thus $w(t)$ is a feasible point for the relaxation. We then discretize the interval $[0,1]$ into 100 discrete points, $t_1, \ldots, t_{100}$, calculate $w(t_i)$ for $i = 1, \ldots, 100$, and numerically solve the PDE constraint in (2.4) using $w := w(t_i)$. Next, we evaluate the objective $J^h(w(t))$ on a $128 \times 128$ mesh and plot $J^h(w(t))$ versus $t$ for the circle, square and rectangle geometries for $\theta = \pi/4$, $\pi/2$, for
a 20 × 20 cloak to demonstrate that the objective function is nonconvex; see Figure 3.

In all cases we see that the objective function is a nonconvex function of \( t \). Because of this nonconvexity, the quasi-Newton method yields only a local minimum. Consequently, we cannot guarantee that the objective associated with the solution of the relaxation found is a valid lower bound on the integer solution. In fact, we observe that even the rounding step can improve/reduce the objective value.

![Graphs showing nonconvexity of the objective function for different shapes and angles](image)

**5.3 Results for the Nominal Problem** Next, we evaluate how well the trust-region method performs from random starting points for all cloaking domains on a 20 × 20 mesh and a 40 × 40 control mesh. For each instance, we create 25 random samples of \( v \in \{0, 1\}^N \), solve for the state, and plot the corresponding objective value. We then use each of these samples \( v \) as a starting guess for our trust-region method, with \( \theta = \frac{\pi}{4} \), and plot the objective at the end. The results are shown in Figure 4.

We observe that not only has the trust-region method reduced the objective function value in all cases but also that the variance of the final objective value, is significantly lower.

Next, we investigate solving the relaxation of (4.1), with TAO for the rectangular domain with \( \theta = \frac{\pi}{2} \) for the 20 × 20 and the 40 × 40 control mesh (Figures 5a and 5d respectively). We note that both the objective function value (Figures 5b and 5e) and the norm of the projected gradient (Figures 5c and 5f) are reduced; in both cases, TAO reduces the projected gradient below \( 10^{-3} \). We also note that the optimal solution for both mesh sizes is similar.

Next, we apply our rounding strategy (4.3) to obtain a rounded solution to use as a feasible starting point for our trust-region method. We have observed numerically that starting the trust-region method with an initial starting point of the rounded relaxation yields a lower objective value when compared to starting the trust-region.
Fig. 4: Trust-region method applied to 25 randomly generated samples for $\theta = \frac{\pi}{4}$ and three cloaking domains. The solid lines show the objective function value at initial guess and the dashed lines of the corresponding color show the objective value after the trust-region method terminated.

Fig. 5: TAO relaxation results on the rectangular region with $\theta = \frac{\pi}{2}$ for $20 \times 20$ control mesh (top row) and $40 \times 40$ control mesh (bottom row).

In Figures 6c and 6f we show a log$_{10}$ plot of the scattering field, log$_{10}(|\mu + \bar{u}\theta|)$, and show that we reduce the integrand of the objective value in the region of interest to a small value. In addition, the gradient over the cloaking region, as shown in Figures 6b and 6e is small, indicating that we have likely found a local optimum to (4.1). We also observe that the final integer cloak is similar to the relaxation, which
indicates that relaxation is a good initial guess. When we compare the final discrete design in Figure 6 with the solution of the continuous relaxation in Figure 5, we note that the two designs are similar.

![Images of solutions and gradients](image-url)

Fig. 6: Results of the trust-region method applied to the rounded relaxation for $\theta = \frac{\pi}{2}$ for cloaking domain $D^1_0$. The top row shows the $20 \times 20$ results, and the bottom row shows the $40 \times 40$ results.

In Figure 7 we show the progress of our trust-region method in terms of objective function values and trust-region radii as a function of iteration for the $20 \times 20$ and $40 \times 40$ control meshes. We observe that our trust-region method is successful at reducing the incumbent objective function for the small trust-region radii regime, making steady improvement.

The complete set of results for the three cloaking domains is shown in the electronic supplement SM1. In Tables 1 and 2 the first column shows the domain and the second column shows the size of the control mesh. We report the CPU time in seconds for our trust-region method in Tables 1 and 2 for the nominal angle $\theta = \frac{\pi}{4}$ and $\theta = \frac{\pi}{2}$, respectively. The tables summarize the computational effort required to solve the MIPDECO. The first three measures show the CPU time of the relaxation solve, the CPU time of the forward (state), adjoint and gradient computation, and the CPU time of the knapsack solve. The CPU time for PDEs/gradient includes computational effort required to build $w(v)$. We include this to highlight the additional computational time required going from $20 \times 20$ to $40 \times 40$ cloak elements, because of the size of each of the respective gradients.

We observe from Tables 1 and 2 that the computation time for solving the knapsack problems, denoted as MIP’s, is negligible. We also observe that the number of trust-region iterations required to meet our termination condition is modest. The trust-region methods time is divided into the amount of time it takes to solve the PDEs, build the gradient, and then solve the knapsack problem. We note that the
number of iterations required to solve (4.1) grows only moderately as we increase the control mesh from $20 \times 20$ to $40 \times 40$, even though the design space grows exponentially.

In Table 3 we report numerical values of the objective associated with the nominal angles $\theta = \pi/4$ and $\theta = \pi/2$. The table contains three values: the relaxed objective, $\hat{J}(u^{\text{relaxed}})$, the rounded relaxation objective function value, $\hat{J}(u^{\text{round}})$, and the trust-region objective function value $\hat{J}(u^{\text{trust}})$. In all simulations we are able to reduce the objective for the circle and square cases to a reasonably small value. The objective associated with the rectangle is much larger by comparison, which is due to its having a larger area. We see in several cases that our trust-region method is able to reduce the objective value. We observe that the relaxed objective function value does not always give a lower bound on the solution. In fact, in some cases, simply rounding already reduces the objective function value. We believe that this behavior is a result of the nonconvexity of our problem.

### 5.4 Results for the Uncertainty Problem

We now present our results for the design under uncertainty, (4.2). In Figure 8 we compare the design found for the $40 \times 40$ instance for a nominal angle of $\theta = \pi/4$ and the design found from solving the uncertainty problem for 15 angles on $[0, \pi/4]$ for $D_0^1$, $D_0^2$, and $D_0^3$. Similar results for the nominal angle of $\theta = \pi/2$ can be found in the electronic supplement SM1. We see a clear difference in design for the rectangle geometry.
Table 2: CPU times(s) for nominal relaxation and PDE solves, as well as trust-region computation on $128 \times 128$ mesh with $\theta = \frac{\pi}{2}$.

Fig. 8: Cloak designs for design under uncertainty using 15 uniformly distributed $\theta \in \left[0, \frac{\pi}{2}\right]$ and for nominal angle $\frac{\pi}{4}$.
In Tables 4 and 5 we repeat the computational effort required to solved the uncertainty simulation for 15 angles. We again take \( \nu(0) = 0.5 \) as a starting guess in TAO. As in the nominal case, solving the relaxation takes the most computational effort compared with the trust-region method. Even though more angles are present in the uncertainty problem, the number of trust-region iterations does not increase drastically. As in the nominal case, the computational time in the trust-region method is dominated by solving the PDEs and constructing the gradient, not by solving the knapsack problems. Another similarity is the number of iterations required by our trust-region method, which increases modestly as we go from optimizing over \( 20 \times 20 \) integer variables to \( 40 \times 40 \). The number of trust-region iterations is not dependent on the number of angles since we see similar iteration counts between a single angle and 15 angles. In the electronic supplement SM1 we include plots for all numerical simulations.

In Table 6, we show the solution quality for the uncertainty case. We see that in many cases, similar to the single angle case, we can reduce the objective function value below the relaxed objective function value, which is due to the nonconvexity of our problem.

We also compare the nominal design to the uncertainty design over a range of angles for the circular domain. We define the function

\[
 f(\hat{\theta}) = \hat{J}^h(\hat{\theta}; v^{\text{trust}}).
\]

We take the solution of the trust-region method from the nominal and the uncertainty case with a given \( \tilde{\theta} \), solve the state, and evaluate the objective value to obtain \( f(\tilde{\theta}) \). We compare the nominal design for \( \theta = \frac{\pi}{4} \) with the uncertainty design found using 5, 10, and 15 angles from the interval \( \left[ 0, \frac{\pi}{2} \right] \) on the \( 20 \times 20 \) and \( 40 \times 40 \) control meshes, respectively. We evaluate \( f \) on \( \tilde{\theta} = \left[ 0, \frac{\pi}{2} \right] \) by breaking the interval into 100 sample points and then plot the resulting objective value as a function of \( \theta \), as shown in in Figure 9. We observe that the nominal design produces a lower objective value at \( \frac{\pi}{4} \) when compared to the uncertain designs, which is expected. However, when we move away from the nominal angle, \( \theta = \frac{\pi}{4} \), we observe that the uncertain design performs better than the nominal design. We built the nominal design to cloak for a single angle, so it makes sense that it is superior to the uncertain design at \( \theta = \frac{\pi}{4} \), which covers several angles. Similarly, because the uncertain design was developed for several angles, it performs better across a range of angles.

6 Conclusions In this paper, we introduced a trust-region method to solve MIPDECO problems. We applied our method, successfully, to construct binary electromagnetic cloaking devices that are effective at inducing electromagnetic cloaking, both for deterministic and uncertain incidence waves. The method uses tools that
are standard in the PDE optimization and mixed-integer programming communities. Our method starts by solving the relaxation, rounds that solution, and then performs a modest number of trust-region iterations. The gradient in our trust-region method is found by using techniques from PDE-constrained optimization. The integer portion of the MIPDECO problem is dealt with in the trust-region subproblem, which is a knapsack problem.
